Determining the death burden for prioritising public health interventions necessitates detailed data on the causal pathways to death. Postmortem minimally invasive tissue sampling (MITS), incorporating histology, molecular and microbial culture diagnostics, enhances cause-of-death attribution, particularly for infectious deaths. MITS proves a valid alternative to full diagnostic autopsies, especially in low- and middle-income countries. In Soweto, South Africa (SA), the Child Health and Mortality Prevention Surveillance (CHAMPS) programme has delineated over 1 000 child and stillbirth deaths since 2017. This SA CHAMPS site supports advocating for the use of postmortem MITS as routine practice, for more granular insights into under-5 mortality causes. This knowledge is crucial for SA's pursuit of Sustainable Development Goal 3.2, targeting reduced neonatal and under-5 mortality rates. This commentary explores the public health advantages and ethicolegal considerations surrounding implementing MITS as standard of care for stillbirths, neonatal and paediatric deaths in SA. Furthermore, based on the data from CHAMPS, we present three pragmatic algorithmic approaches to the wide array of testing options for cost-effectiveness and scalability of postmortem MITS in South African state facilities.

S Afr Med J 2024;114(2):e1538. <https://doi.org/10.7196/SAMJ.2024.v114i2.1538>

There has been a reduction in the global under-5 mortality rate from 93 deaths per 1 000 live births in 1990 to 38 in 2021.^[1] Nevertheless, under-5 mortality rates remain high in low- and middle-income countries (LMICs). Ascertaining the cause of childhood death remains challenging in LMIC settings, and mainly premised on verbal autopsy and vital registration data.^[2] The verbal autopsy tool was developed to establish cause of death where other methods are unavailable, despite the low sensitivity (<33.3%).^[3,4] Determining the cause of death, even in health facilities in LMICs, is often hampered by the scarcity of diagnostic tools, multiple coexisting conditions, and paucity of postmortem sampling of the decedents.^[2,5,6] Furthermore, there is a lack of data on the cause of stillbirths, of which 98% of the 2.6 million annual cases occur in LMICs.^[7] More granular insight into the causes of deaths in children under 5 years of age from LMICs could inform interventions to achieve the Sustainable

Development Goal 3.2 of reducing neonatal and under-5 mortality to as low as 12 and 25 per 1 000 live births, respectively, by 2030.

Complete diagnostic autopsy remains the gold standard for determining cause of death. However, social, cultural and religious factors, including fears of body mutilation or organ removal, and relatively short times to burial related to cultural and religious beliefs, preclude routine use of complete diagnostic autopsies in most LMICs.^[8,9] Further constraints to undertaking complete diagnostic autopsy in LMICs include personnel and laboratory resource constraints, and funding of competing health priorities.^[5] The use of postmortem minimally invasive tissue sampling (MITS) has emerged as a valuable tool in accurately determining cause of death, particularly from infectious causes. Furthermore, the use of MITS is acceptable among LMIC communities, and can be undertaken within a reasonable period following death.^[10,11] A standardised operating

protocol for the MITS procedure using biopsy needles was piloted in Mozambique and is widely used in other programmes.^[12] Findings from Mozambique showed 83% correlation in the cause of death determination using MITS compared with complete diagnostic autopsy, including stillbirths, and in the absence of antemortem clinical data.^[12-14] The Child Health and Mortality Prevention Surveillance (CHAMPS) programme is a multicentre surveillance across seven LMIC settings. CHAMPS aims to determine the causal pathway to death on the causes of stillbirths and under-5 childhood deaths. The investigations in CHAMPS include clinical data abstraction, verbal autopsies and systematic multi-organ MITS, which is submitted for histopathology, molecular and microbiologic diagnostics.^[2]

In this commentary, leveraging on experience with MITS in Soweto, South Africa (SA), we discuss the social and cultural considerations of undertaking MITS and the materialising public health benefits. We provide an argument for the implementation of MITS as a standard-of-care practice in paediatric departments, with the aim of improving diagnostic accuracy of cause-of-death attribution to inform public health and clinical interventions to reduce childhood mortality. Furthermore, based on the data from CHAMPS, we present three pragmatic algorithmic approaches to the wide array of testing options for cost-effectiveness and scalability of postmortem MITS in SA state facilities.

Determining cause of death: Procedure and process

The MITS procedure has been previously described.^[12,15-17] Briefly, following consent from the guardian/parent, the decedent is cleansed with alcohol and iodine solution within 24 hours of death in an unrefrigerated body or within 72 hours if the corpse was refrigerated. Investigation includes photographs of the decedent, measuring of height and weight and tissue sampling. The body organ samples include core biopsy samples from the brain, liver and lungs. Blood is taken by intracardiac puncture, cerebrospinal fluid is collected from below the occipital bone and swabs are taken from nasopharyngeal space and rectum. The entire sampling procedures can be completed within 30 minutes, albeit dependent on the expertise of the technician and the number of sites being sampled.

The cerebrospinal fluid is sent for microscopy, culture and susceptibility (MC&S) testing as well as for multiplexed nucleic acid amplification tests using polymerase chain reactions (PCR) on four custom-designed syndromic TaqMan array cards (TAC; ThermoFisher Scientific, USA).^[16] The TAC cards used in CHAMPS have been designed to detect 116 different pathogens. Blood samples are sent for HIV PCR, malaria thick and thin smears, MC&S and TAC. The rectal swab is sent for GeneXpert MTB and TAC, and nasopharyngeal swab is sent for TAC.^[16] Tissue sampling from lung, liver and brain is done with a core biopsy needle for histopathological assessment and special stains or immunohistochemistry, as guided by the TAC results (Fig. 1). Limitations to the current testing process include the inability to diagnose congenital heart lesions. Kidney sampling could be attempted should the clinician feel that histological confirmation of renal disease would be helpful.

Demographics, clinical findings, antemortem test results, postmortem test results and verbal autopsy are used by the Determination of Cause of Death (DeCoDe) panel for the cause of death ascertainment. The DeCoDe panel consists of local paediatricians, neonatologists, obstetricians and gynaecologists, microbiologists, and anatomical pathologists.^[18] Using the World Health Organization coding of death, the panel ascribe an underlying and an immediate cause of death, and any other causes that are directly or indirectly in the pathway to death.^[19] For deaths attributed to a single condition, that condition is considered the underlying cause of death. For deaths in which more than one

condition played a role, underlying, antecedent and immediate causes are assigned. The underlying cause of death is the condition considered to have precipitated a series of events that ultimately resulted in death. The immediate cause of death is the most proximal event which resulted in the death, and comorbid conditions are events between the underlying and immediate cause of death. A hypothetical example is illustrated in Table 1. The results from the DeCoDe panel are relayed to the family, who are offered grief counselling, and provided any recommendations from the panel to prevent future deaths.

Ethicolegal considerations for conducting MITS in South Africa

According to SA law, persons are entitled to their inherent dignity even when they have demised. The South African Constitution, Section 15(1) states that 'everyone has the right to freedom of conscience, religion, thought, belief, and opinion.'^[21] Respecting the family's choice of their deceased loved ones is to be upheld. Notably, the law permits autopsies

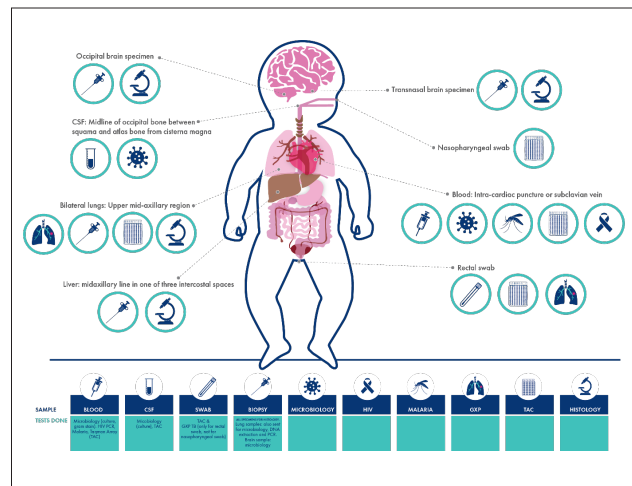

Fig. 1. Infographic showing minimally invasive tissue sampling sites and sampling (image of body with arrows to sites where samples are taken from with exact landmarks indicated). Cerebrospinal fluid: midline of the occipital bone between the squama and the atlas bone from the cisterna magna. Blood: subclavian vein or intracardiac puncture site. Rectal and nasopharyngeal swabs. Tissues: Liver: midaxillary line in one of the three intercostal spaces. Lungs: upper mid-axillary region bilaterally. Brain: transnasally and occipitally. Other skin, hair abnormal tissue or fluid).

Table 1. WHO format used to capture conditions in causal chain of death^[20]

Report	Cause of death*	Time interval from onset to death
Report disease or condition directly leading to death	A <i>Nosocomial sepsis</i> Aetiology: <i>Acinetobacter baumannii</i>	24 hours
Report chain of events in order (if applicable)	B <i>Nosocomial pneumonia</i> Aetiology: <i>A baumannii</i>	24 hours
	C <i>Respiratory distress syndrome</i>	1 week
State underlying cause of death	D <i>Very low birthweight</i>	1 week
Other conditions that did not form part of the causal chain leading to death	<i>HIV exposure</i> <i>Twin pregnancy</i>	

*Italicised text indicates a hypothetical example.

outside ‘other than natural deaths’, with consent from the families. Similarly, upholding human rights to dignity and freedom when considering the MITS procedure is of critical importance.^[21] MITS conducted in the CHAMPS study aligns with SA legislature, as it promotes the respect to human dignity of the deceased as well as the rights of their families.

Furthermore, the ‘right to access healthcare services, including reproductive health care’, and therefore the preventability of death, is recognised in section 27(1)(a) of SA law.^[21] Informed by the results of MITS in CHAMPS, some of the preventable factors of a death include access to high-quality healthcare, appropriate health-seeking behaviours, adequate antenatal care and access to family planning services. This also draws attention to some of the potentially targetable public health measures to reduce childhood mortality.

With regard to autonomy, it is particularly important that the family is not coerced into having the MITS procedure on the deceased. Families are often receptive to the procedure if the principles of improving lives and outcomes of others in the future are made known. In a multi-country mixed-method study, 75% of 194 participants were willing to know the cause of death of a relative, with an additional 16% being willing to know the cause of death only under certain circumstances (e.g. sudden death or unclear clinical diagnoses).^[9] A retrospective survey

in Kenya reported that 81% of people who had previously declined a full autopsy would have consented to MITS.^[22] Unpublished data in Soweto suggest that the mothers of decedents found that the information garnered by MITS in CHAMPS assisted them with closure and initiated their healing processes. Furthermore, mothers’ perceptions were that the timeous undertaking of MITS did not interfere with religious and traditional practices. It is important that the procedure is thoroughly explained to the parents and that details about the sampling are included. This includes a description of the puncture sites and that small needle marks may be visible on the body after the procedure.

Ethically, it is permissible for bodies of the decedents to be used for medical research if it promotes beneficence and will improve the livelihood of those who are living, provided consent has been given. Feasibility of the MITS procedure ensures the bioethical principle of justice by providing people with a clearer understanding of the causes of death of their loved ones.^[21]

The benefits of the results of MITS extend to women who deliver stillbirths, by understanding factors that may have contributed to death. Therefore, MITS fulfils the reproductive rights of women and girls in SA by equipping them with information related to their previous pregnancies, which can inform preventive measures for subsequent pregnancies.

Acceptability of standardisation of MITS among healthcare professionals

Prior studies suggest that 90% of healthcare practitioners found MITS to be either ‘as acceptable’ or ‘more acceptable’ than complete diagnostic autopsy, and that a less invasive procedure would make the process of discussing postmortem examination with parents and relatives easier.^[23] A qualitative study among healthcare workers conducted in India reported that MITS was perceived to offer accurate diagnoses, and might identify less prevalent co-existing illnesses.^[6] Healthcare workers also found MITS acceptable in cases where the diagnosis or cause of death was undetermined in the antemortem period.^[6] Currently, in SA, there are no laws in place that prohibit standardisation of autopsy procedures. The standardisation of the MITS procedure in SA could help alleviate the burden of cost and limited personnel to conduct full autopsies within the SA healthcare system.

The experience gained since 2017 from the CHAMPS study in Soweto has established a valuable foundation that underscores the importance and feasibility of broadly implementing MITS as a standard practice. Nevertheless, there are certain challenges in LMICs that may impede routine deployment of MITS, including the clinical workload of healthcare professionals, the time required to perform MITS and the limited laboratory facilities to undertake testing.^[6] These perceived hurdles to routine use of MITS to investigate the causes of under-5 childhood deaths need to be weighed against the benefit of undertaking the procedure. For example, CHAMPS noted that clinician antemortem diagnosis often differed from the DeCoDe panel, which had access to the MITS results.

Public health benefits of undertaking MITS in LMICs

SA has an extensive backlog of pending complete diagnostic autopsies owing to the high rate of ‘other than natural deaths’ in adults and children, coupled with the scarcity of qualified personnel to perform complete diagnostic autopsies.^[24,25] It is estimated that there are ~70 000 autopsies needing to be performed for medicolegal purposes annually in SA.^[25] The MITS procedure is less complex than a complete diagnostic autopsy and does not require the same level of skill as forensic pathologists. Furthermore, results from MITS can be provided to families in a shorter time, assisting with the grieving process and providing closure and clarity on the cause of the death.^[8]

The dissemination of cumulative cause-of-death results provides an important opportunity for key targeted public health

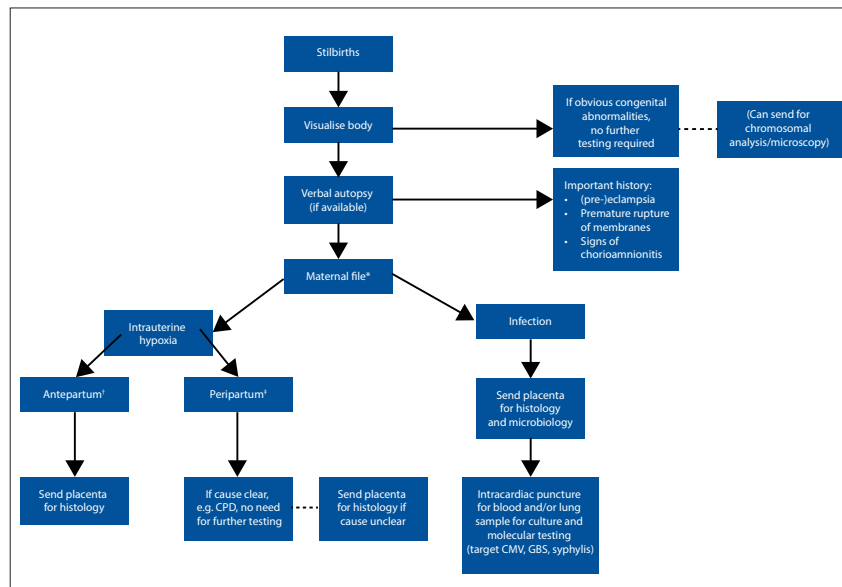

Fig. 2A. Stillbirth algorithm. Histological samples are often autolytic in stillbirths, so assessment is less valuable. Target organisms for molecular testing should be region-specific common viral and bacterial pathogens. If resources allow, a broader spectrum of pathogens can be considered. (CPD = cephalopelvic disproportion; CMV = cytomegalovirus; GBS = group B streptococcus.)

*If maternal file is unavailable then the clinician would need to approach the death broadly as possible intrauterine hypoxic or infectious causes.

†Antepartum refers to cases where no fetal heart rate is detected on presentation the healthcare facility.

‡Peripartum refers to cases where a fetal heart rate was detected on presentation, but the fetus died during delivery.

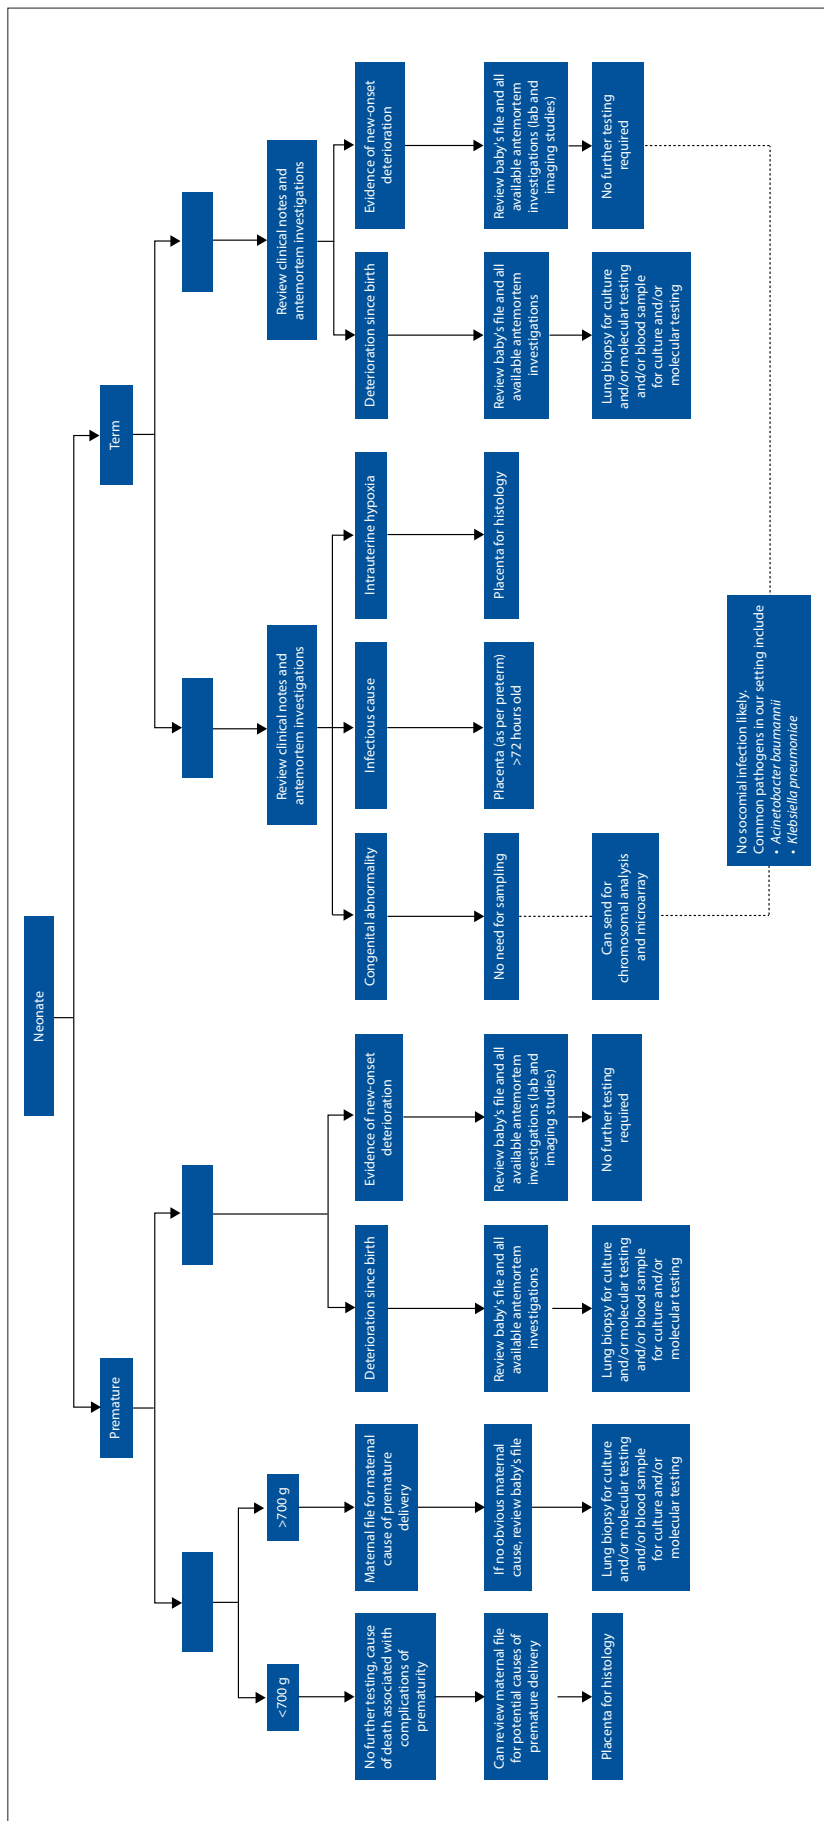

Fig. 2B. Neonate algorithm. If a child is hospitalised for >48 hours and there is evidence of new-onset clinical deterioration, then cause of death is likely a nosocomial infection. No sampling is required, and the diagnosis can be based on ante-mortem data. Sampling in these cases will provide surveillance data. Target organisms for molecular testing should be region-specific common viral and bacterial pathogens. If resources allow, a broader spectrum of pathogens can be considered.

interventions. For example, in Kenya, the launch of the Kisumu County Nutrition Action Plan was informed, in part, by the large number of childhood deaths from underlying malnutrition identified through CHAMPS.^[26] Furthermore, national folate food fortification has been instituted in Ethiopia following the large number of childhood deaths attributable to neural tube defects identified through CHAMPS. In SA, interventions targeted at common hospital-acquired pathogens such as *Klebsiella pneumoniae* and *Acinetobacter baumannii* are being implemented, again informed by the findings from the use of postmortem MITs.^[18] Our experience in CHAMPS has also revealed an increasing number of young mothers not attending antenatal care, and, resultantly, conditions such as syphilis and pre-eclampsia are undiagnosed in the antenatal period. These missed opportunities to seek healthcare offer us the chance to educate local women about the importance of antenatal care and health-seeking behaviour.

Pragmatic approach to MITs in South Africa

The ideal situation would be for extensive testing of all samples; however, MITs as performed in CHAMPS is intensive and costly (~USD609 - 1028).^[27] Given that most public sector hospitals in SA are resource constrained, a cost-effective approach is to limit testing to key informed areas and less for routine surveillance purposes. Based on the data from the CHAMPS study in Soweto, we propose using age-specific algorithms that provide a pragmatic cost-effective approach, albeit with some limitations associated with such rationalisation (Figs 2A-C). Consequently, the clinician or clinical department will ultimately determine the extent of testing depending on the availability of resources. Notably, causes of death may change with time and algorithms may not be generalisable to all regions within SA. Importantly, consent, a verbal autopsy and review of the clinical data will need to be done timeously in non-refrigerated bodies, a limitation for busy low-staffed clinical units.

Stillbirths algorithm

The paucity of data in LMICs on causes of stillbirths has made it difficult to establish effective interventions.^[28] The maternal medical history and placental investigation play a pivotal role in providing more granular evidence of

from the time of birth would require a lung biopsy and blood sample for MC&S to establish whether there was a source of infection that caused the death.

Paediatric algorithm

Deaths following discharge from hospital can be stratified into three different groups: (i) previously well child with no comorbidities; (ii) untreated/virologically unsuppressed HIV or severe acute malnutrition; and (iii) death on arrival to hospital. Unfortunately, MITS cannot accurately diagnose poisoning, and this is a limitation when it comes to more directed sampling.

Decedents with an underlying traumatic incident would not usually require testing, as the underlying cause of death is usually attributed to the traumatic event (e.g. motor vehicle accident). Should the child survive the traumatic event and require a prolonged hospitalisation, their immediate cause of death would then likely be a nosocomial infection, and directed sampling would indicate the causative organism.

In children presenting to a health facility as 'death on arrival' (DOA), the verbal autopsy would be useful to determine further testing. For DOAs without well-documented preceding events, a complete diagnostic autopsy would be recommended. In children with a history of an infectious cause of death, we recommend sampling of blood, cerebrospinal fluid (CSF) and a lung aspirate/biopsy for culture and/or molecular testing.

In a pilot study in Soweto, it was shown that 36% of paediatric cases were HIV exposed at birth, including 13% who were infected with HIV. Furthermore, 62% of the children were malnourished, confirming the magnitude of the immunocompromised paediatric population in Soweto.^[31] Immunocompromised children admitted for >48 hours are prone to hospital-acquired infections, and if resources allow, further testing will provide more granular information of the involved organisms. Community-acquired infections are often the cause of death in these children admitted for <48 hours, and blood, CSF and lung biopsy or culture have been demonstrated to be reliable in our setting for determining the infectious agent. Infection, mainly from pneumonia or sepsis, was found to be the immediate cause of death in 94% of cases where HIV was the underlying cause of death.^[31]

Children who are not immunocompromised commonly present to hospital with signs of sepsis, diarrhoeal disease, or signs of an acute respiratory tract infection.^[31] Our experience has suggested that the best way to investigate these three categories of disease is with blood, CSF and lung culture. Molecular testing, if available, can provide a broader organism identification.

Conclusion

The CHAMPS study has provided an opportunity to better understand the burden of disease in LMICs. Using data-informed pragmatic algorithms, a limited MITS procedure can be cost-effective and scalable in LMICs. The public health benefits and acceptability among the community and healthcare practitioners make this a feasible standard of care practice to improve the assessment of death in children. Efforts to achieve Sustainable Development Goal 3.2 should be targeted at the evolving findings of causes of death in children, neonates and stillbirths. The findings from MITS are providing more granular information on current causes of death, and this could guide further interventions to achieve the Sustainable Development Goals. The long-term impact would result in deaths averted by changes in health-seeking behaviour, antenatal care, and preventable childhood diseases.
